ABSTRACT

Objective: This study examines the impact of telehealth nursing interventions on length of stay (LOS) and ratio of LOS to risk-adjusted length of stay comparing tele-acute and traditional units.

Methods: Retrospective data from 6,999 patient visits at tele-acute and traditional hospital units between Q2 2020 and Q4 2022 were collected. Bivariate analysis and the Mann-Whitney *U* Test were used to determine statistical significance. Multivariate regression was conducted to analyze the factors affecting both LOS and the ratio.

Results: Regardless of the model, the findings suggest that LOS was greater in the traditional unit. In the LOS model, the stay was 7 hours and 39 minutes longer per admission in the traditional unit. In the risk-adjusted ratio model, the LOS was 5 hours and 14 minutes longer per admission than in the tele-acute unit.

Conclusions: This study contributes to a body of literature that is lacking in the use of telehealth nursing in the acute care setting. Our research offers new perspectives on how telehealth can affect operational measures like LOS and discharge times. This contribution is important as it broadens the scope of telehealth's benefits beyond traditional remote care, highlighting its potential in fast-paced, acute care settings.

Key Words: Telemedicine, Telehealth, Tele-acute, Length of stay

1. INTRODUCTION

Telehealth has emerged as a transformative force in health-care, with the potential to improve the quality of healthcare and save lives.^[1,2] Telehealth is typically characterized as the use of telecommunications and information technology (IT) to provide remote access to a health assessment, diagnosis, intervention, consultation, supervision, and information.^[2] While there is limited research on the effects of telehealth interventions on timely patient discharge, length of stay (LOS), and discharge timing, many healthcare organizations have implemented telehealth strategies to monitor patients post-discharge,^[1,3] prevent hospitalization, reduce readmission,^[4-6] and ensure patients comply with prescription regimens.^[7,8] Evidence from these studies suggests that telehealth can significantly enhance care transitions after hospital discharge, patient involvement, and medication adherence.

Given the potential of telehealth to enhance care transitions, it may also play a role in addressing factors that hinder timely hospital discharges. Many healthcare institutions face challenges in discharging patients promptly due to issues such as communication breakdowns, undefined processes, delays in receiving test results, slow execution of discharge orders, and issues related to determining discharge destinations.^[9-12] These barriers contribute to discharge delays across various settings. Delays in discharging patients could contribute to an extended LOS, leading to dissatisfied patients and family members, as well as an increased risk of contracting hospital-acquired infections and congesting patient throughput.^[13,14] As a means of contributing to increased satisfaction, healthcare organizations are continually striving to improve patient discharge efficiency and reduce LOS by implementing various strategies such as using multidisciplinary teams, interdisciplinary rounding processes, and a lean and six-sigma approach.^[10,11,15,16] However, as various organizations are moving towards enhanced discharge planning and reducing LOS, one such intervention that should be considered is the use of telehealth through virtual nursing, with nurses remotely monitoring patients and providing support to nurses physically caring for patients in the unit. Telehealth, particularly reinforced during the COVID-19 pandemic, has shown potential for enhancing patient and family satisfaction by providing cost-effective, high-quality care.^[17,18]

We deployed virtual nursing in a tele-acute unit of an academic medical center (AMC) located in the southeastern United States. Virtual nurses were required to have a minimum of two years of clinical experience, and, in addition to patient interventions, were charged with mentoring any newly graduated nurses performing bedside care for patients on the telehealth unit. The interventions of the virtual nurses

were aimed at increasing efficiency and timeliness, while decreasing the workload of the bedside nurse. The virtual nurse involvement included assisting with completing most of the intake process and risk assessments including pressure ulcers, falls, deep vein thrombosis, and peptic ulcer disease, in addition to completing virtual rounds to assess patient needs and environment. These interventions reduced pressure injuries by 60% and falls by 65% in the tele-acute unit, according to internal quality improvement studies. Virtual nurses assisted with lab review through communicating critical and concerning labs to the bedside team and monitoring blood glucose levels and treatments. Additionally, the virtual nurses helped with assessments that included level of comfort, pain assessment, and restraints. The telehealth nurses were also involved in ensuring the accuracy of medication orders and delivery by assessing if the physician orders matched the notes concerning the patient's plan of care and what the patient is receiving, as well as checking for duplicate orders, medication compliance, and any contraindications between medications and patient condition. Finally, the telehealth nurses assisted with medication reconciliation as part of the admission process, in addition to providing any necessary medication education to patients and families throughout their inpatient stay. Given that discharge planning should begin at admission, we predicted that these telehealth interventions would positively impact the timeliness of the discharge process by allowing the bedside nurse to better focus on discharge promoters and barriers.

In this study, we aim to examine the impact of virtual nursing interventions on LOS and ratio of LOS to risk-adjusted-LOS (RAE-LOS) in a tele-acute unit and a traditional unit. We hypothesize that a tele-acute intervention in nursing care led to better clinical outcomes, specifically in terms of LOS and the ratio of actual LOS to RAE-LOS. For LOS, we examine the difference between actual LOS and RAE-LOS, with RAE-LOS being projected by a Vizient[®] risk-adjusted model based on individual patient billing codes and demographic information.

2. METHODS

2.1 Data collection

Retrospective data were collected from a tele-acute and traditional units from an AMC located in the southeastern United States. A total of 6,999 visits were obtained between the second quarter of 2020 and the fourth quarter of 2023. The distribution of visits between the tele-acute unit and traditional unit is 3,679 and 3,320, respectively. Each encounter in the data represents a patient visit, with duplicate visits counting as unique encounters, and includes admission and discharge dates, actual LOS, RAE-LOS, time from order to

discharge, and the type of inpatient unit. The ratio between actual LOS and RAE-LOS is calculated. If the ratio is larger than 1, it means a patient stayed more time than projected, and if it is less than 1, it means the patient stayed less time than projected. Prior to performing the tests and regression analysis, missing values and outliers were identified and removed, resulting in a dataset of 135 observations. Summary statistics of the cleaned data are included in Table 1.

Table 1. Summary statistics of cleaned data

Feature	Average ± standard deviation (range) for numerical features, % for categorical features	
Order to discharge min	847.10 ± 3,319.30 (2.73-27,506.03)	
LOS	7.26 ± 4.10 (0.92-18.81)	
Risk adj LOS	6.48 ± 2.43 (2.17-12.59)	
Ratio	1.18 ± 0.68 (0.25-5.01)	
Nurse Unit	Tele-Acute	63.18%
	Traditional	36.82%
Readmission Risk Score	High Risk	41.36%
	Low Risk	23.18%
Living Situation	Moderate Risk	18.64%
	Not Appropriate	16.82%
Insurance Group	With Family	72.86%
	Alone	22.11%
	Other	5.03%
	Government Programs	66.82%
	Commercial Insurances	26.82%
	Financial Assistance	5.91%
	Other	0.45%

Note. LOS: Length of stay

2.2 Statistical analysis

The statistical analysis was conducted in two steps. First, a bivariate analysis was performed by comparing the mean LOS and the ratio of LOS to RAE-LOS for the two units (tele-acute and traditional) using line charts at quarterly bands. Additionally, the Mann-Whitney *U* Test was used to determine if there were statistically significant differences between the two units with respect to the LOS and the ratio.

In the second step, multivariate linear regression was conducted to analyze the factors affecting both LOS and the ratio. This analysis aimed to quantify the impact of various variables, including hospital setting and readmission risk score, on LOS and the ratio. Log transformation was applied to the dependent variables to achieve normally distributed residuals.

2.3 Mann-Whitney *U* Test

The goal of the analysis was to determine whether there was a significant difference between the two units (tele-acute and traditional) with respect to the actual LOS and the ratio of LOS to RAE-LOS. Since the data were collected from the same hospital, it is assumed that the two units have equal variance. The Shapiro-Wilk test confirmed that LOS and the ratio are not normally distributed. Therefore, the Mann-Whitney *U* test was employed to compare differences between the two groups (tele-acute and traditional). The test was conducted separately for LOS and the ratio of actual LOS to RAE-LOS. The hypotheses for the Mann-Whitney *U* test were as follows:

- Null Hypothesis (H0): The LOS and ratio for tele-acute unit are not significantly less than for the traditional unit.
- Alternative Hypothesis (H1): The LOS and ratio for tele-acute unit are significantly less than for traditional unit.

2.4 Multivariate regression

To further investigate the relationship between the dependent variables (LOS and ratio) and independent variables (hospital setting), two multivariate linear regression analyses were conducted at the encounter level. The regression models aim to quantify the effect of each variable on LOS and ratio. The regression analysis helps to understand how the hospital setting influences the dependent variables (LOS, ratio) and to quantify the magnitude of these effects.

3. RESULTS

3.1 Line chart comparison

Line charts were used to compare the LOS and the ratio of LOS to RAE-LOS between the tele-acute and traditional units banded by quarter. Figure 1 shows the quarterly changes in the ratio of LOS to RAE-LOS for both units from Q2 2022 to Q4 2023. Overall, the ratio for the tele-acute unit is lower than the traditional unit across most quarters, indicating that the tele-acute patients stay less time than predicted. This is also explained by the actual LOS chart in Figure 2 for both units over the same period. Figure 2 shows that the LOS for tele-acute patients remains lower than that for traditional patients in most quarters, suggesting that patients in the tele-acute unit tend to have shorter stays compared to those in the traditional unit.

3.2 Mann-Whitney *U* Test Results

The Mann-Whitney *U* test was conducted to compare the LOS and the ratio of actual LOS to RAE-LOS between the tele-acute and traditional units (see Table 2). For the LOS, the test resulted in *p*-value of .17, indicating no statistically significant difference in LOS between the tele-acute and

traditional units. Consequently, we fail to reject the null hypothesis, suggesting no statistical significance between the tele-acute and traditional unit for LOS. In contrast, the Mann-Whitney *U* test for the ratio of actual LOS to RAE-LOS produced a *p*-value of .015, indicating a statistically significant difference in the ratio between the tele-acute and traditional units. Thus, we reject the null hypothesis, concluding that the ratio for the tele-acute unit is statistically significantly less than for the traditional unit. This means that in the tele-acute unit, patients tend to stay less time than would be predicted by the Vizient® model.

3.3 Multivariate linear regression results

Two multivariate regression models were developed at the encounter level, focusing on LOS and the ratio of LOS to RAE-LOS, respectively. Log transformation was applied to the dependent variables to achieve normally distributed residuals.

Figure 1. Mean of Ratio of tele-acute vs. traditional per quarter

Figure 2. Mean LOS of tele-acute vs. traditional per quarter

3.4 LOS model

For the LOS model, the “Nurse Unit” variable had a statistically significant positive coefficient (Coefficient = 0.319, *p*-value = .001), indicating that being in the tele-acute unit is associated with a lower log-transformed LOS compared to the traditional unit (see Table 3). Specifically, the log-transformed LOS increases by 0.319 when the patient is in the traditional unit, holding other variables constant. This

means that tele-acute unit patients have lower LOS than traditional unit patients. Specifically, the log-transformed LOS increases by 0.319 days when the patient is in the traditional unit, holding other variables constant. When exponentiated ($\exp [0.319] \approx 1.38$), this translates to the LOS in the traditional unit being 1.38 times the LOS in the tele-acute unit, suggesting that patients in the traditional units stayed about 7 hours and 39 minutes longer than those in the tele-acute unit.

Table 2. Summary of Mann-Whitney *U* test results

Feature	Average ± standard deviation (range) for numerical features, % for categorical features	
Order to discharge min	847.10 ± 3,319.30 (2.73-27,506.03)	
LOS	7.26 ± 4.10 (0.92-18.81)	
Risk adj LOS	6.48 ± 2.43 (2.17-12.59)	
Ratio	1.18 ± 0.68 (0.25-5.01)	
Nurse Unit	Tele-Acute	63.18%
	Traditional	36.82%
Readmission Risk Score	High Risk	41.36%
	Low Risk	23.18%
	Moderate Risk	18.64%
	Not Appropriate	16.82%
Living Situation	With Family	72.86%
	Alone	22.11%
	Other	5.03%
Insurance Group	Government Programs	66.82%
	Commercial Insurances	26.82%
	Financial Assistance	5.91%
	Other	0.45%

Note. LOS: Length of stay

The “Order to Discharge” variable did not show statistical significance related to the log-transformed LOS (Coefficient = 0.000, *p*-value = .436). In terms of readmission risk scores, being in the “Other” category was associated with a statistically significantly higher log-transformed LOS (Coefficient = 0.330, *p*-value = .020). However, the “Low Risk,” “Moderate Risk,” and “Not Appropriate” categories did not affect the log-transformed LOS in a statistically significant way.

Living situation and insurance group generally did not have statistically significant effects on the log-transformed LOS. The exceptions were that “financial assistance” and “government programs” had no statistically significant impact on LOS compared to commercial insurance, while being in the “Other” insurance category also did not significantly affect the log-transformed LOS.

Table 3. Regression analysis for LOS and ratio

Variable	LOS Model			Risk-adjusted Ratio Model			
	Coefficient LOS	p-value LOS	Asterisks LOS	Coefficient ratio	p-value ratio	Asterisks ratio	
Nurse Unit	0.319	.001	***	0.214	.007	**	
Order to Discharge (min)	0.000	.436	ns	0.000	.718	ns	
Readmission Risk Score (base = High Risk)	Low Risk	0.028	.806	ns	0.075	.441	ns
	Moderate Risk	-0.098	.414	ns	-0.070	.491	ns
	Not Appropriate	0.288	.183	ns	0.187	.310	ns
Living Situation (base = Alone)	Other	0.108	.627	ns	-0.085	.655	ns
	With Family	0.067	.488	ns	-0.020	.806	ns
Insurance Group (base = Commercial Insurances)	Financial Assistance	0.157	.426	ns	0.055	.745	ns
	Government Programs	-0.089	.351	ns	-0.168	.040	*
	Other	-0.069	.881	ns	0.069	.860	ns
R-squared	0.896			0.10			

Note. ns: Not statistically significant; * indicates statistically significant variables; LOS: Length of stay

3.5 Risk-adjusted ratio model

For the risk-adjusted ratio model, the “Nurse Unit” variable had a statistically significant positive coefficient (Coefficient = 0.214, *p*-value = .007), indicating that being in the tele-acute unit is associated with a lower log-transformed ratio of LOS to RAE-LOS compared to the traditional unit. Specifically, the log-transformed ratio increases by 0.214 when the patient is in the traditional unit, holding other variables constant. This confirms that patients in the tele-acute unit stay less time than those who are in the traditional unit. When exponentiated ($\exp [0.214] \approx 1.24$), the coefficient indicates that the ratio of actual LOS to projected LOS in the traditional unit being approximately 1.24 time the ratio in tele-acute unit, suggesting that patients in the traditional unit stayed about 5 hours 14 minutes longer than those in the tele-acute unit.

The “Order to Discharge” variable did not have a statistically significant affect on the log-transformed ratio (Coefficient = 0.000, *p*-value = .718). Among the readmission risk scores, being in the “Other” category was associated with a statistically significantly higher log-transformed ratio (Coefficient = 0.334, *p*-value = .006). The “Low Risk,” “Moderate Risk,” and “Not Appropriate” categories did not affect the log-transformed ratio in a statistically significant way.

Living situation did not demonstrate statistical significance related to the log-transformed ratio. Categories “Other” and “With Family” had coefficients of -0.085 (*p*-value = .655) and -0.020 (*p*-value = .806), respectively, indicating no statistically significant impact compared to living alone. Insurance group had one statistically significant finding: being covered by government programs was associated with a statisti-

cally significantly lower log-transformed ratio (Coefficient = -0.168, *p*-value = .040), with the ratio being approximately 15% lower than for patients with commercial insurance. Financial assistance and being in the “Other” insurance category did not affect the log-transformed ratio in a statistically significant way.

The *R*-squared value for the LOS model is 0.896, indicating that approximately 89.6% of the variance in LOS is explained by the variables included in the model, suggesting a strong model fit. In contrast, the *R*-squared value for the ratio model is 0.10, indicating that only 10% of the variance in the ratio is explained by the variables included in the model, suggesting a weak model fit.

4. DISCUSSION

This study examined the impact of virtual nursing in a tele-acute care unit in a large AMC in the southeastern United States relative specifically to time from order to discharge, LOS, and the ratio of actual LOS and RAE-LOS. To do this, we compared two acute care units: tele-acute and traditional. This study contributes to a body of literature that is lacking in the use of telehealth nursing in the acute care setting, and more specifically its contribution in transitions of care. Our findings are indirectly consistent with the literature demonstrating various improvements across the care continuum post-discharge.^[1,3,7,8] Our research offers new perspectives on how telehealth can affect operational measures like LOS and discharge times. This contribution is important as it broadens the scope of telehealth’s benefits beyond traditional remote care, highlighting its potential in fast-paced, acute care settings.

Our findings indicate that telehealth interventions in the tele-acute unit demonstrate statistically significantly impact the LOS and the ratio of actual LOS to RAE-LOS compared to the traditional unit. We observed in consecutive quarters that patients stayed shorter than projected in the tele-acute unit compared to the traditional unit. We conducted two different analyses using the LOS Model and the Ratio Model. These models were applied at the encounter level to examine the relationship between LOS and the ratio of actual to RAE-LOS across both units (tele-acute and traditional).

The findings from the LOS Model showed that the tele-acute unit had a shorter LOS than the traditional unit. There are several indirect implications on healthcare delivery and outcomes. Prolonged hospital stays, as documented in the literature, are associated with an increased risk of hospital-acquired infection and adverse patient outcomes.^[19] Insurers often do not cover the costs associated with these extended stays and consequent complications, thereby financially impacting hospitals.^[19] The average daily cost of an acute care bed at the institution is between \$1,200 and \$1,500, per departmental leadership. Our study showed that the LOS in the traditional unit was 1.38 times longer than in the tele-acute unit. Based on these figures, the potential daily cost implication ranges from approximately \$1,656-\$2,070 per admission. Furthermore, a longer LOS in the hospital exacerbates throughput challenges, leading to a bottleneck effect.^[12, 16] This bottleneck effect causes patients in the emergency department to face delays in admission or even initial evaluations due to the unavailability of beds downstream on the care units.^[12, 16]

There is also an indirect impact on emergency department operations and staff well-being. If patients stay longer in these units, ER nurses will be required to manage acute care patients for extended periods, which diverges from their primary training in rapid patient assessment and stabilization. This misalignment in job function may lead to increased stress and burnout, negatively affecting staff retention rates.^[20] This underscores the importance of strategically improving patient flow and resource allocation to enhance overall healthcare efficiency and quality.

On the Ratio Model, we also found that being in the tele-acute unit was associated with a lower log-transformed ratio of LOS to RAE-LOS compared to the traditional unit. The model also showed that patients stayed shorter than expected in the tele-acute unit compared to the traditional unit. This finding suggests that discharge planning should be initiated at the time of admission to reduce potential unexpected extended stays, which is consistent with the literature.^[12, 16, 21, 22] Additionally, increasing resources, such as

employing more tele-nurses, might improve efficiency and patient flow in the traditional units. However, the ratio model should be interpreted cautiously, as only 10% of the variance in the ratio is explained by the variables included in the model.

In light of the findings, this study had some limitations. This study was conducted in an AMC. AMCs are often thought to be resource rich with study findings that are not generalizable beyond the AMC environment. The impact of tele-interventions on LOS might be more pronounced in a lower resource setting. The study was conducted in the southeastern United States, potentially limiting generalizability to other geographic regions. The representativeness of our findings may be limited due to a substantial reduction in our data sample caused by numerous missing variables. This reduction in sample size could affect our results' reliability and generalizability, as well as the findings themselves. Additionally, the ratio model had an *R*-squared value of 0.10, meaning it only explains 10% of the variance in the ratio. Findings from the ratio model should be interpreted with caution. We also did not account for the role of other providers — like care managers and social workers — who often play a critical role in discharge planning and patient flow management. Many health systems depend on these professionals to organize discharges, address social needs, and connect patients with follow-up care. Since our data do not capture their involvement in either the tele-acute or traditional units, it is possible that some of their contributions to LOS and discharge outcomes were not reflected in our results. As a result, our findings might not fully capture the collaborative efforts that impact LOS and discharge efficiency. Future research would benefit from including data on these providers to offer a complete picture of the factors influencing LOS and patient outcomes. There is complexity in accurately measuring all factors influencing LOS and discharge timing. Variables, such as unit-specific discharge procedures, rounding schedules, staffing levels, and other operational processes, can vary and are not easily captured through chart reviews alone. Although we accounted for some relevant factors, such as patients' living situations and insurance coverage, other unmeasured variables may have influenced discharge outcomes. This limitation highlights the challenge of drawing definitive conclusions about LOS based solely on chart data. Future research incorporating qualitative data or operational metrics could provide a more comprehensive understanding of the factors influencing LOS and discharge efficiency. Lastly, while not necessarily a limitation, it is worth noting that the implementation of the telehealth unit was initiated in the second quarter of 2020, just after COVID-19 had been declared a pandemic. It is not known how this timing impacted the

early data, but data from around the second quarter 2022 (about 24 months post-implementation) are consistent with declining LOS data specifically relative to COVID-19.^[23]

5. CONCLUSION

This study makes a strong association between the use of telehealth nurses and LOS and the ratio of LOS to RAE-LOS. These findings show that integrating telehealth may contribute to more efficient patient management, leading to earlier discharges and potentially reducing the burden on healthcare systems. Our findings add valuable insights to the emerging literature on telehealth applications in acute care, demonstrating that telehealth can significantly improve operational efficiencies such as discharge times and LOS. Overall, this study underscores the significant potential of telehealth to transform acute care delivery, improve patient outcomes, and optimize hospital resource utilization.

ACKNOWLEDGEMENTS

The authors acknowledge the expert revisions suggested by the reviewers. Those revisions helped to provide clarity to this study and resulted in an overall better manuscript.

AUTHORS CONTRIBUTIONS

SSF, EW, TS, AA and EEB originally conceptualized the project. AA analyzed data and wrote applicable parts of the paper.
